(Received 9 February 2005; revised manuscript received 1 August 2005; published 23 September 2005)

We study stationary patterns arising from a combination of flow and diffusion in a two-dimensional (2D) reaction-diffusion system in a channel with Poiseuille flow. Both transverse and longitudinal modes are investigated and compared with numerical computations.

DOI: 10.1103/PhysRevE.72.036216 PACS number(s): 82.40.Bj

I. INTRODUCTION

Flow- and diffusion-distributed structures (FDS) are stationary periodic patterns that appear in reaction-diffusion systems with open flow if a constant perturbation from a uniform steady state is applied at the inlet [1,2]. Unlike Turing patterns [3] and differential-flow instability (DIFI) [4], such structures can be observed even for identical diffusion and flow rates of the reactants. The mechanism of formation of these structures was discovered theoretically by Kuznetsov et al. [1] and subsequently Andresen et al. [2] identified its important role as a new model of pattern formation. Soon after the theoretical discovery these structures were first obtained in an experiment by Kærn and Menzinger [5]. They studied a system without differential transport and, to underline the kinematic nature of the observed patterns, referred to them as flow-distributed oscillations (FDO). The role of differential transport was later studied by Satnoianu et al. [6,7] and by McGraw and Menzinger [8]. Generalized structures of this kind became known as FDS, and Míguez et al. [9] carried out the first experimental observation of such structures. Now FDS patterns attract much interest. Theoretical [10–13] and experimental [14–17] studies have addressed different properties of these structures. Also, the FDS mechanism is relevant in biological systems [18,19].

All previous theoretical studies of FDS were made for a 1D model system. Experiments were also carried out for systems with negligible transverse variations in flow rate and chemical concentrations [5,14,15]. This situation is rather artificial and in our paper we introduce a more realistic 2D model that employs a channel with a parabolic velocity profile (Poiseuille flow [20]).

The only experiment with a Poiseuille flow was published by Kærn and Menzinger [5]. The experiment was unsuccessful and Kærn and Menzinger concluded that flow-distributed oscillations cannot be obtained in a system with a parabolic velocity profile. However, we believe that this problem should be studied in more detail and in the present paper the possible existence of such structures is examined numerically and analytically.

II. FORMULATION

We consider as a model system the 2D version of the well-known Lengyel-Epstein equations for the CIMA (chlorite-iodide-malonic acid-starch) reaction [7,21,22]:

\[ u_t + \Phi(y)u_x - \Delta u = a - u - 4uv/(1 + u^2), \]  

\[ v_t + \Phi(y)v_x - \delta \Delta v = b[u - uv/(1 + u^2)]. \]

Here \( u = u(x,y,t) \) and \( v = v(x,y,t) \) are the dimensionless dynamical variables related to the interacting chemical species, \( a > 0 \) and \( b > 0 \) are constant parameters related to the chemical species, \( \Delta \) is the 2D Laplacian, and \( \delta > 0 \) is the ratio of the diffusion rates for \( v \) and \( u \). Subscripts denote partial derivatives and \( \Phi(y) \) is the velocity profile of the flow along the channel in the \( x \) direction. For Poiseuille flow,

\[ \Phi(y) = \phi(1 - y^2/h^2), \quad -h \leq y \leq h, \]

where \( \phi > 0 \) is the central flow rate and \( 2h \) is the width of the channel. The geometry of our model is shown in Fig. 1. At the walls of the channel it is assumed that the flux of chemical species vanishes:

\[ u_y(x,y = \pm h,t) = v_y(x,y = \pm h,t) = 0. \]

The system (1)–(3) admits the homogeneous steady-state solution \( u_s = a/5, \quad v_s = 1 + a^2/5^2 \). In the absence of flow \( (\Phi = 0) \) this is destabilized by the Hopf or Turing modes whose growth rates become positive at the critical points,

\[ b_H = (3a^2 - 125)/(5a) \]  

and

\[ b_T = \delta[125 + 13a^2 - 4a\sqrt{10(25 + a^2)}]/(5a), \]
Note that the 1D case the FDS domain coincides with the Hopf domain [3]. Note that instability occurs for values of $b$ below the critical points (4) and (5).

In the 1D case, where (2) is replaced by $\Phi=\phi$ with $\phi$ constant, FDS solutions are obtained by applying a constant perturbation at the inlet. The transition to FDS takes place if the flow rate is above a critical value. The results of a linear stability analysis show that the critical flow rate and corresponding wave number are [1,2,12]

$$\phi_{\text{FDS}} = \sqrt{\frac{40a^3b(\delta + 1)^2 - (3a^2\delta + 5ab - 125\delta)^2}{(25 + a^2)(\delta + 1)(3a^2 - 5ab - 125)}}, \quad (6)$$

$$k_{\text{FDS}} = \sqrt{\frac{(3a^2 - 5ab - 125)}{(25 + a^2)(\delta + 1)}}. \quad (7)$$

Note that $\phi_{\text{FDS}}$ diverges and $k_{\text{FDS}}$ vanishes at $b=b_H$, i.e., in the 1D case the FDS domain coincides with the Hopf domain [6].

III. NUMERICAL RESULTS

In this section we report the numerical solutions of (1)–(3). The solutions are obtained using the Peaceman-Rachford method of variable directions [23]. To produce pattern formation in our 2D flow system, we apply constant boundary conditions at the inlet,

$$u(x=0,y,t) = u_S + U_{\text{bnd}}(y), \quad (8a)$$

$$v(x=0,y,t) = v_S + V_{\text{bnd}}(y), \quad (8b)$$

where at least one of the profiles $U_{\text{bnd}}(y)$ and $V_{\text{bnd}}(y)$ is nonzero. In most of the numerical experiments reported here a uniform inlet perturbation is taken and, in general, it is assumed that $U'_{\text{bnd}}(y=\pm h)=V'_{\text{bnd}}(y=\pm h)=0$, consistent with (3). Also, an outlet condition $(u_{xx}, v_{xx})|_{x=0}=0$ is applied, where $X$ is the length of the reactor.

Typically, in numerical experiments with our 2D model stationary patterns of two types are encountered: stripes transverse to the flow and longitudinal stripes. Transverse solutions correspond to $y$-dependent versions of FDS in 1D systems, while longitudinal ones are specific to the 2D case.

Figure 2 shows some typical transverse patterns obtained when the flow rate is sufficiently high. In Fig. 2(a) the width of the reactor is small ($h=1.5$) and the pattern is similar to that of a 1D FDS structure. The transverse stripes are uniform, i.e., have almost constant width and only slight curvature associated with the $y$ dependence of the flow. However, an increase in the value of $h$ results in some significant changes. Figure 2(b) shows the transverse pattern for $h=6.5$. The stripes are now nonuniform. In the middle they are thick with more or less constant width and small curvature whereas the ends are thin and more curved. This suggests the development of a boundary-layer structure as $h \to \infty$.

The mechanism of transverse pattern formation is similar to that of the 1D case. These patterns appear in the Hopf instability domain. Flow and diffusion are responsible for the distribution of the Hopf oscillation in space while the constant condition at the inlet fixes the initial phase and provides the stationarity of the pattern. In addition, transverse diffusion synchronizes the solution across the channel so that the pattern extends into the regions of slow flow near the walls.

Our simulations show that, similar to the 1D case, the transverse solution appears when the flow rate is above a critical value $\phi$, and that the corresponding critical wave number $k_t$ is nonzero. The behavior of $\phi_t$ and $k_t$ as functions of $h$ is quite interesting and is analyzed in Sec. IV.

Figure 3 illustrates a longitudinal solution. Figure 3(a) shows how the stationary pattern forms behind a moving
critical point for the transverse solution. Simultaneously, the interaction between them results in the formation of complicated patterns. The longitudinal solutions with odd indices correspond to an axially symmetric structure and are difficult to observe because they require the use of more complicated inlet profiles. However, even when the transverse and longitudinal modes appear simultaneously, the interaction between them results in the formation of complicated patterns. Figure 5 presents an example of this. In Fig. 5(a) the flow rate is far below the critical value, and the space is occupied by the longitudinal stripe that exists at any flow rate. Odd solutions, as shown in Fig. 4, are produced when the inlet profile is uniform in the y direction. The number of stripes in the longitudinal solution depends on h. It is convenient to count these solutions with index n. This index gives the number of inflections of u and v in the y direction so that n+1 is the number of lighter and darker stripes. An even index corresponds to an axially symmetric profile u(y) = u(y), while an odd index corresponds to a profile with odd symmetry u(y) = -u(y). For the solutions in Fig. 3, n = 6.

The longitudinal solutions with n odd are difficult to observe when the inlet profiles are uniform in y because they force the axially symmetric modes of the system. Odd inlet profiles, however, can produce odd solutions, as shown in Fig. 4, where use of the step function at the inlet results in the growth of odd solutions with n = 1 and n = 3. Higher odd values of n require the use of more complicated inlet profiles because these solutions are more easily damped by the even modes.

When the transverse and longitudinal modes appear simultaneously, the interaction between them results in the formation of more complicated patterns. Figure 5 presents an example of this. In Fig. 5(a) the flow rate is far below the critical point for the transverse solution φ, and the space is occupied by the longitudinal stripe that exists at any φ. The toothlike pattern along the edges of the stripe is nonstationary and travels in the x direction. In Fig. 5(b) the transverse solution appears, since φ exceeds the critical value φ. The

longitudinal solution is still admitted and, being partially damped, is manifested as a raised area along the axis of the reactor.

Figure 6 shows another example of the interaction between the modes: a remarkable spot pattern appears as a combination of longitudinal and transverse structures. Note that here different mechanisms of pattern formation act in the x and y directions, leading to a new type of spot formation. This is different from the classical spots associated with the Turing instability only.

IV. LINEAR ANALYSIS

In this section we use a linear analysis to investigate conditions for the appearance of stationary solutions. Neglecting temporal dependence, we consider a solution to Eqs. (1) representing a small deviation from the basic state: u(x,y,t) = u₀ + U(y)e^{iφ}, v(x,y,t) = v₀ + V(y)e^{iφ}, where q is, in general, complex. Then U(y) and V(y) satisfy the equations

\[ U'' = [qΦ(y) - q^2 - j_{11}]U - j_{12}V, \]

(9a)

FIG. 4. Odd longitudinal solutions forced by the inlet profiles \( U_{\text{bd}}(y) = 0.5 \sin(y) \) and \( V_{\text{bd}}(y) = 0 \). a = 30, b = 12, \( δ = 9, φ = 10 \). (a) \( h = 1.5, n = 1 \), (b) \( h = 4.5, n = 3 \).
where primes denote derivatives in y and \( j_{nm} \) are the coefficients of the Jacobian matrix. \( j_{11} = 3 - 20b/(25 + a^2) \), \( j_{12} = -20a/(25 + a^2) \), \( j_{31} = 2a^2b/(25 + a^2) \), and \( j_{22} = -5ab/(25 + a^2) \). In addition, the boundary conditions,

\[
U'(y = \pm h) = V'(y = \pm h) = 0,
\]

should be satisfied.

Transverse modes are periodic in \( x \), so that, in general, Im \( q = k \neq 0 \) and Re \( q = 0 \). Substituting \( q = ik \) into Eqs. (9), we obtain a two-point boundary-value problem that has a nontrivial solution at specific values of \( \phi = \phi_i \) and \( k = k_i \). The eigenvalues \( \phi_i > 0 \) and \( k_i \neq 0 \) are the critical flow rate and wave number, respectively, of the transverse solution. We search for the eigenvalues \( \phi_i \) and \( k_i \) numerically by a shooting method [25] which reduces the problem to locating the zeros of a \( 4 \times 4 \) determinant.

Figure 7 presents a numerical solution to the two-point boundary-value problem (9) and (10). Figure 7(a) shows the critical flow rate \( \phi_i \) as a function of \( h \) and Fig. 7(b) shows the corresponding wave numbers \( k_i \). Labels 1 and 2 indicate different values of \( b \). It can be shown from (9) and (10) that

\[
\phi_i \rightarrow 3\phi_{FD}/2 \quad \text{and} \quad k_i \rightarrow k_{FD},
\]

as \( h \rightarrow 0 \), equivalent to the fact that for small \( h \) the average flow rate \( (2h)^{-1}\int_0^h \Phi(y)dy \) must exceed \( \phi_{FD} \). From Eqs. (6) and (7), this gives \( \phi_i \rightarrow 9.566 \) and \( k_i \rightarrow 0.458 \) as \( h \rightarrow 0 \) for case 1, and \( \phi_i \rightarrow 4.187 \), \( k_i \rightarrow 0.642 \) as \( h \rightarrow 0 \) for case 2. An extrapolation of the numerical values obtained in Fig. 7 produced agreement with these results to within a relative precision of \( 10^{-5} \).

Figure 7 shows that the transverse solution contains at least two branches. In case 1, corresponding to a higher value of \( b \), the branches are separated with a gap where nondecaying transverse structures do not exist. The critical flow rate diverges at the edges of the gap while the wave number vanishes. When \( b \) becomes smaller, as in case 2, the branches overlap and the gap degenerates to a single point of intersection. Dashed segments of the curves correspond to transverse structures that are not, in general, selected by the system.

The numerical results of Fig. 2 correspond to either side of the gap in case 1. Figure 2(a) corresponds to the structure below the gap that is similar to a 1D FDS pattern with slight curvature in \( y \), and Fig. 2(b) illustrates the structure that appears above the gap, where there are nonuniform transverse stripes. It is possible that the parameters used in the Poiseuille flow experiment by Kærn and Menzinger [5] correspond to the gap in solutions, and so stationary transverse structures were not observed.

The gap can be found from the conditions at its edges \( \phi_i \rightarrow \infty, k_i \rightarrow 0 \). Substituting \( k_i = 0 \) and \( \psi = \phi_i k_i \) into Eqs. (9) and keeping Re \( q = 0 \), we obtain a new boundary-value problem for the gap edges \( h_{gap} \). Figure 8 presents \( h_{gap} \) as a function of \( b \). When \( b \) is decreased, the lower boundary approaches the upper one and they merge. Below this point the nonuniform transverse stripes appear before the point at which \( \phi_i \) diverges and, as a result, the gap degenerates into a point.

Figure 7 shows only two branches of the transverse solution. The accurate numerical solution of the system (9) and (10) requires significant computational resources, especially as \( h \) increases. It is possible that a further investigation at higher values of \( h \) may reveal more branches with gaps or intersection points, but this is beyond the scope of the present study.

Let us now consider longitudinal modes. These are uniform in \( x \) and hence \( q = 0 \). Contrary to the previous case, the transition to the longitudinal solution is not controlled by the flow rate, and the eigenvalue problem (9) and (10) determines \( h \) as a function of \( \delta, a, \) and \( b \). It has a nontrivial solution \( h = nh_i \) \( (n = 1, 2, 3, \ldots) \), where \( h_i = \pi/(2k_{FD}) \) and

\[
k_{FD}^2 = [\pm \sqrt{(3a^2 \delta + 5ab - 125\delta)^2 - 160a^2b^2 + 3a^2\delta - 5ab - 125\delta}/(2\delta(25 + a^2))]\).

The requirement for \( h_i \) to be real means that \( k_{FD}^2 \) should be real and positive. Thus, there is a critical point when the
square root vanishes, provided the rest of the expression is positive. Another critical point appears if \( k_{\perp} \) or \( k_{\parallel} \) vanishes. However, it can be shown that this happens when the determinant of the Jacobian matrix of the system is zero, which is not relevant for a reaction-diffusion system. Here, the critical point for CIMA obtained from (12) is \( \delta = \delta_i \), where

\[
\delta_i = \frac{5ab[125 + 13a^2 + 4a\sqrt{10(25 + a^2)}]}{(125 - 3a^2)^2}.
\]  

A longitudinal solution appears when \( \delta > \delta_i \), i.e., this type of solution requires the differential diffusion to be sufficiently high. It can be shown that the identical critical value of \( \delta \) is given by the equation \( b = b_T \), where \( b_T \) is the Turing critical point (5). Hence, we conclude that the longitudinal solution is the Turing structure that fits within the channel walls.

Each \( k_{\parallel} \) in (12) produces a series of longitudinal modes with profiles,

\[
U(y), V(y) = \begin{cases} 
\sin[yn \pi/(2h)], & \text{for odd } n, \\
\cos[yn \pi/(2h)], & \text{for even } n,
\end{cases}
\]  

where \( n \) is the index of the longitudinal mode introduced in Sec. III. The eigenfunctions (14) can be used as inlet profiles to produce the longitudinal solutions with either an odd or even index. This works well in the numerical simulations, although this would be difficult to arrange experimentally.

In the nonlinear system higher harmonics can allow satisfaction of the boundary conditions (10) even if \( h \) does not exactly match the spectrum \( nh_i \). Thus, \( nh_i \) gives the lower bound of \( h \) for which the longitudinal solution with corresponding index \( n \) is admitted. In particular, the smallest eigenvalue \( h_i = \pi/(2k_{\parallel}) \) determines the minimum size of the reactor for which longitudinal solutions are allowed at all.

\[ \text{V. SUMMARY} \]

In this brief paper we have presented a preliminary investigation of FDS patterns in a 2D reaction-diffusion-advection system with a parabolic flow profile. Pattern formation in this system is shown to take place via two mechanisms. The first is a \( y \)-dependent version of the 1D FDS mechanism that breaks the symmetry in \( x \) along the flow. The diffusion and flow generate a spatial oscillation whose initial phase is frozen by a constant inlet condition. This results in transverse stripes similar to 1D FDS patterns. The second mechanism breaks the symmetry in \( y \) and the Turing instability produces a solution homogeneous in \( x \) that fits within the sidewalks of the channel.

The longitudinal pattern separates the reactor into areas where the concentrations of the species remain constant along the flow. It is important to note that this takes place even if the inlet distributions of the concentrations are uniform. This symmetry-breaking effect resulting in the dynamical separation of the species may be useful for experimental studies as well as in industrial processes.

When both mechanisms of pattern formation are engaged, a combination of transverse and longitudinal structures results in some interesting and complex patterns. In particular, remarkable spot patterns are observed. The 1D FDS mechanism is already known to be relevant in biological systems as a model for axial segmentation [18,19], and it is likely that the present results can also be interpreted in this context.

We believe that our results can be reproduced for other model systems and observed in experiments, although further work is first needed to examine the stability of the solutions found here. A more detailed analysis will be presented in subsequent papers.
